Resumo

Mantém-se uma discrepância persistente entre as métricas padrão de Avaliação da Qualidade de Imagem (IQA) e os juízos perceptivos humanos, geralmente quantificados através dos Mean Opinion Scores (MOS). Esta divergência constitui um desafio central em aplicações onde a qualidade percebida afeta o desempenho, como no reconhecimento facial. Apresentamos uma nova métrica de Avaliação da Qualidade de Imagens Faciais (FIQA) sem referência, desenvolvida no âmbito de uma estrutura de aprendizagem do tipo Full-to-No-Reference. O processo tem início com um modelo de fusão com referência completa, treinado para fazer a regressão de métricas IQA clássicas em função dos MOS humanos num subconjunto anotado. Este modelo é então utilizado para gerar pseudo-MOS para o conjunto completo de dados. Estes rótulos supervisionam depois um regressor profundo sem referência baseado em características extraídas da ResNet-18, originando uma métrica alinhada com a percepção humana que estima a qualidade diretamente a partir de imagens faciais degradadas. Testámos a nossa abordagem no contexto de imagens faciais afetadas por esteganografia, demonstrando a sua eficácia em cenários com distorções subtis e anotações humanas limitadas.

Abstract

A persistent gap remains between standard Image Quality Assessment (IQA) metrics and human perceptual judgments, typically quantified via Mean Opinion Scores (MOS). This poses a key challenge in applications where perceived quality impacts performance, such as facial recognition. We introduce a new no-reference Face Image Quality Assessment (FIQA) metric, developed within a Full-to-No-Reference learning framework. The process begins with a full-reference fusion model trained to regress classical IQA scores against human MOS on a labeled subset. This model is used to generate pseudo-MOS scores for the full dataset. These labels then supervise a no-reference deep regressor based on ResNet-18 features, producing a perceptually aligned metric that estimates quality directly from distorted facial images. We tested our approach in the context of steganographically degraded facial images, showing its effectiveness in scenarios involving subtle distortions and limited human annotations.

"O que acontece no Mundo é que toda a gente que nasce, nasce de alguma maneira poeta. Inventor de qualquer coisa que não havia no Mundo ainda, antes deles nascerem. E inteiramente individual. Cada um poeta que é!"

3.1	Partitioning of the steganographically distorted dataset.	24
3.2	Demographic and non-demographic profile of the observers.	26
3.3	ANOVA [100] results for observer and image attributes. Before debiasing, several factors show statistically significant effects on MOS, p-value < 0.05. After residualization, all main effects show no significant impact, confirming the effectiveness of the debiasing procedure.	30
3.4	Performance of our Fusion metric and the selected FR-IQA metrics. Higher PLCC and SRCC indicates better correlation with MOS. Lower MSE and MAE indicate more accurate quality estimates.	34
3.5	Performance of our pMOS-Face compared to standard NR-IQA baselines.	35

1 Introduction

1.1 Contextualization

Image quality refers to the degree to which a visual representation meets perceptual or functional expectations. It is typically associated with the presence or absence of distortions, artifacts, or degradations that affect how an image is perceived by humans or processed by machines. High-quality images preserve structural, textural, and color information in a way that aligns with human visual preferences or supports reliable computer vision performance [1], [2].

Image Quality Assessment (IQA) is the process of quantifying image quality in a systematic and reproducible way. It plays a central role in optimizing image acquisition [3], compression [4], transmission [5], and restoration pipelines [6]. IQA metrics aim to provide reliable quality estimates that correlate well with human perception [7], [8]. Due to the complexity of human vision and its subjective nature, building computational models that accurately reflect perceived quality remains a challenging task.

IQA metrics are generally categorized as subjective or objective. Subjective assessment involves human observers who rate the perceived quality of images, typically following standardized protocols such as ITU-R BT.500 [9]. While subjective metrics are considered the gold standard due to their direct alignment with human perception, they are time-consuming, expensive, and not scalable. In contrast, objective metrics rely on computational models to estimate image quality automatically, aiming to approximate human judgment with high consistency and low cost [1], [10].

Subjective image quality assessment relies on human evaluations to generate ground-truth perceptual scores, often in the form of Mean Opinion Score (MOS) or Difference Mean Opinion Score (DMOS). These scores are typically collected under controlled conditions following international standards such as ITU-R BT.500 (International Telecommunication Union — Radio-communication Sector Recommendation — Broadcasting service — Television [9]. Subjective assessment captures nuances of human vision that are difficult to model algorithmically, making it essential for validating and benchmarking objective IQA models [10], [11]. However, it is

inherently limited by inter-observer variability, cultural or demographic bias, and the logistical costs associated with large-scale studies [12]. Crowdsourcing platforms like Amazon Mechanical Turk [13] have recently enabled more scalable data collection, though at the expense of environmental control and consistency.

Objective IQA methods are commonly divided into three categories: full-reference (FR), reduced-reference (RR), and no-reference (NR). FR-IQA assumes access to an undistorted reference image and compares it to the distorted version using perceptual models [7], [14], [15]. RR-IQA methods extract partial information from the reference image, enabling a compromise between performance and practicality [16], [17]. NR-IQA, also known as blind IQA, operates without any reference and is considered the most challenging, requiring models to infer quality based solely on the distorted image [18], [19].

Facial Image Quality Assessment (FIQA) is a specialized subfield of IQA that aims to quantify the quality of facial images with respect to their utility in downstream biometric or analytic tasks. Unlike general-purpose IQA, FIQA must account for both perceptual attributes (e.g., blur, noise) and task-specific considerations such as facial pose, occlusion, expression, and alignment [20], [21], [22]. High-quality face images are crucial for ensuring the accuracy and fairness of face recognition systems, particularly in security, forensics, and surveillance domains [23], [24]. Consequently, FIQA models often incorporate features from deep face recognition networks to align quality predictions with identity discrimination performance [25]. This task-oriented nature of FIQA makes it fundamentally different from traditional perceptual quality assessment.

FIQA systems have been shown to produce different quality scores depending on a person’s age, gender, or skin tone [25], [26]. These differences often happen because the training data includes more examples from certain groups and fewer from others. For example, images of people with darker skin or non-frontal poses are often less common in training sets, which leads to lower quality scores for those individuals [27]. This can cause face recognition systems to perform worse for some groups than others, raising serious concerns about fairness.

The International Civil Aviation Organization [28] (ICAO) and the ISO/IEC 19794–5 standard [29] establish guidelines for image quality in Machine-Readable Travel Documents (MRTDs). These guidelines ensure uniform image conditions (e.g., lighting, focus, and resolution) and consistency across datasets. While these regulations establish a technical baseline, they do not account for perceptual biases and demographic variability in FIQA.

The ethical implications of these biases are profound. Political regulations, such as the European Convention on Human Rights (Article 14) [30], the Universal Declaration of Human Rights (Article 7) [31], the General Data Protection Regulation (Article 22) [32], and emerging

AI governance frameworks, such as the European Artificial Intelligence Act (2024) [33] and proposals in the USA [34], aim to prevent discriminatory decisions. Despite these efforts, biases persist, often introduced through the human observers who evaluate facial images for FIQA algorithms.

Evidence from neuroscience further supports the complexity of facial image perception. The fusiform face area, a specialized region in the human brain, is selectively activated by face stimuli [27], [35]. This biological specialization makes FIQA particularly sensitive to both stimulus features (e.g., age, gender, ethnicity, attractiveness) and the demographic background of the observers.

An even greater challenge arises when evaluating the quality of steganographically distorted facial images. Steganography is the practice of concealing information within digital media, typically by subtly modifying pixel values in a way that is imperceptible to human observers [36]. Although visually unobtrusive, these alterations can degrade biometric features and compromise recognition performance. NR-IQA approaches, while not requiring references, are generally not designed to detect such imperceptible, task-relevant distortions.

A particularly relevant subclass of steganography for identity documents is printer-proof steganography, which embeds information in a way that remains intact through the print-scan process [37], [38]. These techniques aim to survive real-world transformations such as color shifts, compression, and physical degradation, while maintaining visual fidelity. However, even when such methods are visually imperceptible, they can induce subtle frequency-domain changes or spatial artifacts that disrupt face recognition systems. Assessing image quality in this context requires NR-IQA methods that are sensitive not only to perceptual degradation but also to recognition-relevant cues.

1.2 Problem Statement

Despite significant advances in FIQA, current approaches struggle to capture task-specific degradations introduced by modern steganographic techniques. Existing methods often rely on hand-crafted features [39], supervised quality learning [40], [41], [42], or rank-based formulations [43]. However, these frameworks are typically trained on standard datasets and are not optimized to handle distortions that preserve visual fidelity while disrupting utility. Moreover, demographic and perceptual biases embedded in training data [44] raise concerns about the fairness and generalizability of FIQA systems. This is especially problematic for applications involving MRTDs, where regulation mandates consistent quality but does not address ethical or perceptual variance [28], [29]. Therefore, there is a critical need for NR-IQA methods that can detect

subtle, high-impact degradations in facial images, particularly those arising from adversarial steganography while accounting for demographic fairness and interpretability.

Traditional IQA frameworks tend to generalize across domains, but real-world applications demand task-aware assessment strategies. In the context of facial biometrics, image quality must be evaluated not only in terms of visual fidelity but also in terms of its impact on recognition performance and fairness. This motivates the development of application-specific IQA pipelines that consider context-dependent factors, such as demographic variability and task utility. At the same time, the perceptual dimension of image quality remains central. Human observers are still used as the ground truth in subjective assessments [45], [46], yet NR-IQA models often diverge from these judgments, especially in complex scenarios involving subtle degradations or diverse populations. To bridge this gap, new strategies are needed to align NR-IQA with subjective perception, either by integrating perceptual priors, modeling bias sources, or learning from pseudo-MOS annotations that reflect human preferences [47], [48].

To address the limitations of existing approaches, we propose a NR-IQA framework tailored to facial images affected by subtle or task-relevant distortions, such as those introduced by steganography. Our method relies on a fusion strategy that combines multiple FR metrics, trained using supervised regression against a curated set of subjective scores. This fused metric serves as a proxy ground truth to guide the learning of a NR-IQA model, enabling it to approximate perceptual quality without requiring access to pristine reference images. The framework is evaluated across a steganographically augmented dataset of facial images, incorporating multiple embedding levels and distortion types. By integrating perceptual fidelity, recognition utility, and robustness to imperceptible alterations, the proposed approach seeks to bridge the gap between unbiased human perception and automatic assessment.

2 Related Work

2.1 Subjective IQA

Subjective image quality assessment is grounded in human visual perception and remains the gold standard for evaluating visual fidelity. Standardized by ITU-R BT.500 [45] and ITU-T P.910 [49], traditional methodologies rely on controlled laboratory conditions, calibrated displays, and predefined rating procedures to ensure reproducibility and validity.

2.1.1 Assessment Protocols

Subjective image quality assessment protocols are divided into two types: quality assessment, which captures the overall perceived quality of an image, and impairment assessment, which evaluates the degradation relative to a reference. These are implemented using two principal methodological paradigms: the Single Stimulus (SS) method, where each image is rated independently, and the Double Stimulus (DS) method, where two images are shown and rated comparatively.

Rating scales may be numerical or categorical. Numerical scales range from 1 to 5, 1 to 11, or 0 to 100, and are used to express either quality (e.g., excellent to bad) or impairment (e.g., imperceptible to very annoying). Categorical scales use labeled intervals and are commonly found in ITU protocols. The choice of scale depends on the desired sensitivity and interpretability of the results.

Each test consists of a set of L individual presentations, each corresponding to the application of test condition j to image or sequence k , potentially repeated r times. For each presentation, subject i provides a discrete score u_{ijk} , forming a matrix of evaluations of dimension $N \times L$, where N is the number of observers. The Mean Opinion Score (MOS) for a given presentation is defined as:

$$\text{MOS}_{jkr} = \frac{1}{N} \sum_{i=1}^N u_{ijk} \quad (2.1)$$

Global MOS values can be obtained by averaging across repetitions or test instances. In double-stimulus protocols, the Difference Mean Opinion Score (DMOS) is computed as:

$$\text{DMOS}_{jkr} = \text{MOS}_{\text{ref},jkr} - \text{MOS}_{\text{dist},jkr} \quad (2.2)$$

To quantify uncertainty in MOS or DMOS, a 95% confidence interval is computed using the sample standard deviation:

$$S_{jkr} = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (u_{ijk} - \bar{u}_{jkr})^2} \quad (2.3)$$

The confidence interval is then given by:

$$\text{CI}_{95} = 2 \cdot \frac{S_{jkr}}{\sqrt{N}} \quad (2.4)$$

This interval assumes a Gaussian distribution of scores and indicates that the true population mean lies within the range with 95% probability. When averaging across multiple images, caution is advised as inter-image variability can dominate the standard deviation in small datasets.

If the raw scores have been transformed, e.g., through boundary compensation or conversion to impairment response functions, the confidence intervals must be recomputed using transformed variables. In this case, the standard deviation becomes a function of each point on the transformed scale, and the confidence bands must reflect the statistical behavior of the mapped domain.

After computing the initial MOS values, the dataset must undergo observer screening to eliminate unreliable participants whose scoring patterns deviate significantly from the overall distribution. According to ITU-R BT.500-15 [45], a kurtosis-based post-screening method is recommended for DSIS, DSCQS, and other alternative methods (excluding SSCQE), especially in studies with relatively few observers (e.g., $N < 20$) or non-expert participants.

For each presentation defined by condition j , image or sequence k , and repetition r , the following statistics are computed: mean score, $\bar{u}_{jkr}$; standard deviation, S_{jkr} ; and kurtosis coefficient, $\beta_{2,jkr}$, given by:

$$\beta_{2,jkr} = \frac{m_4}{(m_2)^2}, \quad \text{where } m_x = \frac{1}{N} \sum_{i=1}^N (u_{ijk} - \bar{u}_{jkr})^x \quad (2.5)$$

If $2 \leq \beta_{2,jkr} \leq 4$, the distribution is considered normal. Otherwise, it is treated as non-normal. For each observer i , two counters are defined: P_i and Q_i , which count the number of times an observer's score is an outlier above or below the acceptable range, respectively.

The outlier detection criteria per presentation are as follows:

If the distribution is normal:

$$\begin{cases} u_{ijkr} \geq \bar{u}_{jkr} + 2S_{jkr} & \Rightarrow P_i = P_i + 1 \\ u_{ijkr} \leq \bar{u}_{jkr} - 2S_{jkr} & \Rightarrow Q_i = Q_i + 1 \end{cases}$$

If non-normal:

$$\begin{cases} u_{ijkr} \geq \bar{u}_{jkr} + \sqrt{20} S_{jkr} & \Rightarrow P_i = P_i + 1 \\ u_{ijkr} \leq \bar{u}_{jkr} - \sqrt{20} S_{jkr} & \Rightarrow Q_i = Q_i + 1 \end{cases}$$

After processing all presentations, observer i is rejected if:

$$\frac{P_i + Q_i}{L} > 0.05 \quad \text{and} \quad \left| \frac{P_i - Q_i}{P_i + Q_i} \right| < 0.3$$

where L is the total number of presentations.

This procedure ensures that only observers with balanced and statistically consistent scoring behavior are retained.

2.1.2 Crowdsourcing

Beyond laboratory-controlled protocols, crowdsourcing has emerged as a scalable alternative for subjective IQA. Platforms such as Amazon Mechanical Turk (AMT) and Prolific allow researchers to gather perceptual scores from a geographically and demographically diverse participant pool. To mitigate the loss of environmental control, studies often integrate reliability checks, such as repeated image pairs or gold-standard trials [46]. While the quality of crowdsourced labels may vary, prior work has shown that when properly filtered, crowdsourced MOS can achieve correlation levels comparable to those from lab-based assessments [48]. This approach enables the creation of large-scale IQA datasets, significantly expanding the empirical foundation for training and benchmarking objective metrics.

2.1.3 Benchmark Datasets

Several benchmark datasets have been curated to support the development and evaluation of IQA models. The LIVE [50], TID2008 [51], TID2013 [52], and CSIQ [53] datasets follow ITU-R BT.500-compliant procedures, providing high-quality MOS or DMOS annotations across a wide range of synthetic distortion types. These datasets have been widely adopted in traditional full-reference IQA benchmarking. Later contributions like Waterloo IAA [54], SIQAD [55], and KADID-10k [56] introduced more diverse or high-resolution distortions and helped identify limitations in classical metrics across complex degradation scenarios. Recent efforts such

as PIPAL [57], KonIQ-10k [58], and SPAQ [59] leverage crowdsourced annotations to capture perceptual variability in the wild. These datasets support the training and evaluation of modern deep learning-based IQA models, particularly in no-reference settings. Despite this progress, domain-specific datasets remain scarce. This limits the generalizability of learned metrics to critical real-world tasks where distortion impacts functional performance rather than only perceived quality.

2.2 Objective IQA

Objective IQA refers to the automatic estimation of visual quality using computational models. Unlike subjective methods that rely on human ratings, objective IQA provides consistent, scalable evaluations suitable for real-world tasks such as compression, transmission, restoration, and enhancement [60], [61]. A wide range of objective metrics has been proposed, reflecting different assumptions about the human visual system and the nature of image distortions. Surveys such as Wang et al. [62], Liu et al. [63], and Ding et al. [64] review dozens of existing metrics, highlighting both classical signal-based models and recent learning-based approaches. While no metric perfectly matches human perception, objective methods offer a low-cost, repeatable alternative for benchmarking, model optimization, and large-scale quality monitoring.

These metrics can be further characterized by the domain in which they operate and the spectral representation they use. The domain refers to the signal space employed during computation. Classical metrics operate in the spatial domain, comparing pixel intensities directly, as seen in PSNR and SSIM [65]. Others use the frequency domain, employing transforms such as the discrete cosine transform (DCT) or wavelet decompositions to capture structural differences, as in VIF [1] and IFC [66]. A third group targets the spectral domain, often used in remote sensing, where images are compared across multiple wavelength bands using metrics such as ERGAS [67] and SAM [68]. Additional domains include gradient-based methods that emphasize edge strength or direction, such as GMSD [69], and deep feature domains, which assess perceptual similarity using activations from convolutional neural networks trained on natural images, as in LPIPS [70] and DISTS [64].

The spectral representation, or color spectrum, denotes the channel configuration used by the metric. Many classical approaches focus solely on the luminance channel (Y), which aligns closely with human perception [1], [71]. Others compute scores over grayscale or full RGB images, as seen in FSIM [72] and its color extension FSIMc. Some metrics operate in alternative color spaces such as YCbCr or CIELab [73], while hyperspectral or multiband metrics process dozens of spectral channels, particularly in remote sensing applications [74], [75]. Table 2.1 summarizes

the 40 IQA metrics considered in this work, detailing their reference type, computational domain, publication year, number of tested databases, and spectral characteristics.

Table 2.1: Summary of the 40 IQA metrics used

Metric	Type	Year	Tested Databases
MSE [60],	Error-based	—	LIVE, CSIQ, TID2008, TID2013
RMSE [60],	Error-based	—	LIVE, CSIQ, TID2008, TID2013
MAE [60],	Error-based	—	LIVE, CSIQ, TID2008, TID2013

2.2.1 Full-Reference IQA

FR-IQA models estimate the perceptual quality of a distorted image by comparing it to an undistorted reference. These methods assume complete access to the original image and are commonly used in contexts where ground-truth data is available, such as image compression, transmission, enhancement, and restoration [61], [62]. By directly quantifying deviations from the reference, FR-IQA provides a consistent and interpretable benchmark for evaluating distortion. However, their applicability is limited to scenarios where high-quality reference images exist, making them unsuitable for many real-world applications [58], [76].

Error-Based Metrics

Error-based metrics quantify distortion by measuring direct numerical differences between the reference and the distorted image. Let $X = \{x_i\}_{i=1}^N$ and $Y = \{y_i\}_{i=1}^N$ be two images with N pixels each. The pixel-wise error can be defined as $E = \{e_i\}_{i=1}^N$, where $e_i = x_i - y_i$.

The most basic error-based metric is the Mean Squared Error (MSE) [60], which quantifies the average squared difference between corresponding pixels in the reference and distorted images:

$$\text{MSE} = \frac{1}{N} \sum_{i=1}^N (x_i - y_i)^2 \quad (2.6)$$

Other related metrics include the Root Mean Squared Error (RMSE), which is simply the square root of MSE, and the Mean Absolute Error (MAE), which averages the absolute differences:

$$\text{RMSE} = \sqrt{\text{MSE}} \quad (2.7)$$

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |x_i - y_i| \quad (2.8)$$

The Peak Signal-to-Noise Ratio (PSNR) expresses the ratio between the maximum possible pixel value and the MSE, typically in decibels (dB):

$$\text{PSNR} = 10 \cdot \log_{10} \left(\frac{MAX^2}{\text{MSE}} \right) \quad (2.9)$$

where MAX is the maximum pixel value (e.g., 255 for 8-bit images).

For block-based compression artifacts, PSNR-B introduces a blocking effect factor (BEF):

$$\text{PSNR-B} = 10 \cdot \log_{10} \left(\frac{MAX^2}{\text{MSE} + \text{BEF}} \right) \quad (2.10)$$

The Signal-to-Noise Ratio (SNR) compares the total signal power to the noise power:

$$\text{SNR} = 10 \cdot \log_{10} \left(\frac{\sum x_i^2}{\sum (x_i - y_i)^2} \right) \quad (2.11)$$

In remote sensing and hyperspectral imaging, metrics such as the Spectral Angle Mapper (SAM) and ERGAS are used. SAM measures the angle between spectral vectors:

$$\text{SAM} = \cos^{-1} \left(\frac{\langle x, y \rangle}{\|x\| \cdot \|y\|} \right) \quad (2.12)$$

ERGAS quantifies the relative global error between multiband images:

$$\text{ERGAS} = 100 \cdot \frac{h}{l} \cdot \sqrt{\frac{1}{N} \sum_{i=1}^N \left(\frac{\text{RMSE}_i}{\mu_i} \right)^2} \quad (2.13)$$

where h and l are the spatial resolutions of the high and low resolution images, RMSE_i is the RMSE for band i , and μ_i is the mean of the reference band.

These error-based metrics are computationally efficient and interpretable, but often correlate poorly with human perception, especially when structural or semantic content is preserved despite pixel-level differences.

The Mean Squared Error (MSE) [60] measures the average squared pixel-wise difference:

$$\text{MSE} = \frac{1}{N} \sum_{i=1}^N x_i - y_i^2 \quad (2.14)$$

The Root Mean Squared Error (RMSE) is the square root of MSE:

$$\text{RMSE} = \sqrt{\text{MSE}} \quad (2.15)$$

The Mean Absolute Error (MAE) computes the average of absolute differences:

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |x_i - y_i| \quad (2.16)$$

The Peak Signal-to-Noise Ratio (PSNR) expresses the logarithmic ratio between the maximum possible signal value and the MSE between a reference and a distorted image:

$$\text{PSNR} = 10 \cdot \log_{10} \left(\frac{MAX^2}{\text{MSE}} \right) \quad (2.17)$$

where MAX is the maximum possible pixel value (typically 255 for 8-bit images). Although widely used for its simplicity and interpretability, PSNR correlates poorly with human perception, especially in the presence of structured distortions.

To address this limitation, PSNR-B extends the original formulation by incorporating a blocking effect factor (BEF), which penalizes compression artifacts such as those introduced by block-based codecs:

$$\text{PSNR-B} = 10 \cdot \log_{10} \left(\frac{MAX^2}{\text{MSE} + \text{BEF}} \right) \quad (2.18)$$

The Signal-to-Noise Ratio (SNR) compares the signal power to the noise power:

$$\text{SNR} = 10 \cdot \log_{10} \left(\frac{\sum x_i^2}{\sum (x_i - y_i)^2} \right) \quad (2.19)$$

The Spectral Angle Mapper (SAM), often used in hyperspectral imagery, computes the angle between image vectors:

$$\text{SAM} = \cos^{-1} \left(\frac{\langle x, y \rangle}{\|x\| \cdot \|y\|} \right) \quad (2.20)$$

The ERGAS (Erreur Relative Globale Adimensionnelle de Synthèse) metric expresses relative global error and is frequently used in image fusion and remote sensing:

$$\text{ERGAS} = 100 \cdot \frac{h}{l} \cdot \sqrt{\frac{1}{N} \sum_{i=1}^N \left(\frac{\text{RMSE}_i}{\mu_i} \right)^2} \quad (2.21)$$

where h and l are the spatial resolutions of the high and low resolution images respectively, RMSE_i is the RMSE of band i , and μ_i is the mean of the reference band.

These metrics are particularly useful when high pixel fidelity is essential, but they often fail to align with human perception, especially in cases where structural or semantic information is preserved.

Perceptual Similarity Metrics

Perceptual similarity metrics aim to model the characteristics of the human visual system (HVS), focusing not on raw signal differences but on how distortions affect perceived quality. These models evaluate structural, luminance, and contrast relationships within local regions of the image and are typically more aligned with subjective scores than purely fidelity-based metrics [62], [71]. The Structural Similarity Index (SSIM) is a foundational method in this category, comparing local windows between the reference and distorted images. Multiscale variants such as MS-SSIM [77] improve robustness across spatial resolutions. Other models, such as FSIM [78], incorporate phase congruency and gradient information to better reflect visual saliency, while GMSD [69] measures image quality by analyzing the standard deviation of gradient magnitude similarity. Additional extensions include SR-SIM [79], which prioritizes salient regions, and W-SSIM [80], which introduces perceptual weighting across scales. These methods offer improved correlation with human opinion scores, particularly in the presence of structural or perceptual distortions.

The Structural Similarity Index (SSIM) compares local image patches between the reference and distorted images, measuring similarity in luminance, contrast, and structure. It is defined as:

$$\text{SSIM}(x, y) = \frac{(2\mu_x\mu_y + C_1)(2\sigma_{xy} + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)(\sigma_x^2 + \sigma_y^2 + C_2)} \quad (2.22)$$

where μ_x and μ_y are the local means, σ_x^2 and σ_y^2 are the local variances, σ_{xy} is the local covariance, and C_1, C_2 are stabilizing constants.

Multiscale SSIM (MS-SSIM) extends SSIM by computing similarity at multiple image scales. It is defined as:

$$\text{MS-SSIM}(x, y) = \prod_{j=1}^M [l_j(x, y)]^{\alpha_j} \cdot [c_j(x, y)]^{\beta_j} \cdot [s_j(x, y)]^{\gamma_j} \quad (2.23)$$

where l_j , c_j , and s_j are the luminance, contrast, and structure comparisons at scale j , and α_j , β_j , γ_j are weights.

The Feature Similarity Index (FSIM) combines phase congruency (PC) and gradient magnitude (GM) to evaluate perceptual quality:

$$\text{FSIM}(x, y) = \frac{\sum_{i \in \Omega} T(i) \cdot PC_m(i)}{\sum_{i \in \Omega} PC_m(i)} \quad (2.24)$$

where $T(i)$ is a similarity function combining gradient and phase congruency similarity at pixel i , and $PC_m(i)$ is the maximum phase congruency across both images.

The Gradient Magnitude Similarity Deviation (GMSD) is based on the standard deviation of pixel-wise gradient similarity maps:

$$\text{GMS}(i) = \frac{2G_x(i)G_y(i) + C}{G_x(i)^2 + G_y(i)^2 + C} \quad (2.25)$$

$$\text{GMSD}(x, y) = \sqrt{\frac{1}{N} \sum_{i=1}^N (\text{GMS}(i) - \overline{\text{GMS}})^2} \quad (2.26)$$

where $G_x(i)$ and $G_y(i)$ are gradient magnitudes of the reference and distorted images, and C is a small constant.

The Spectral Residual Similarity Index (SR-SIM) evaluates similarity by combining spectral residual saliency and gradient magnitude:

$$\text{SR-SIM}(x, y) = \frac{\sum_{i \in \Omega} S_r(i) \cdot G_m(i) \cdot Q(i)}{\sum_{i \in \Omega} S_r(i) \cdot G_m(i)} \quad (2.27)$$

where $S_r(i)$ is the spectral residual saliency map, $G_m(i)$ is the gradient magnitude, and $Q(i)$ is the local structural similarity.

The Information-Weighted Structural Similarity Index (IW-SSIM) assigns greater importance to image regions that carry more structural information. The final score is a weighted average of SSIM values computed at each local window:

$$\text{IW-SSIM}(x, y) = \frac{\sum_{i=1}^N w_i \cdot \text{SSIM}_i(x, y)}{\sum_{i=1}^N w_i} \quad (2.28)$$

where w_i is the information weight for window i , often computed using local entropy or local variance.

The Wavelet-based SSIM (W-SSIM) extends SSIM into the complex wavelet domain. Instead of operating directly on image intensities, it evaluates phase consistency across wavelet subbands. The general form follows a similar structure to SSIM, applied to wavelet coefficients:

$$\text{W-SSIM}(x, y) = \prod_s \prod_o \text{SSIM}(x_{s,o}, y_{s,o}) \quad (2.29)$$

where s indexes the scale and o the orientation in the wavelet decomposition, and $x_{s,o}$ and $y_{s,o}$ are the corresponding coefficients.

The Edge Strength Similarity Metric (ESSIM or ESIM) modifies SSIM by replacing the structure component with a comparison of edge magnitudes. The edge strength is typically extracted via a Sobel or Prewitt operator. The structure term σ_{xy} is replaced by a directional edge similarity $E(x, y)$, such that:

$$\text{ESSIM}(x, y) = \frac{(2\mu_x\mu_y + C_1)(2E(x, y) + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)(E(x, x) + E(y, y) + C_2)} \quad (2.30)$$

where $E(x, y)$ denotes the dot product of edge maps from the two images.

While perceptual similarity metrics approximate human visual perception by analyzing structural and saliency-based cues, they remain largely deterministic and handcrafted.

Information-theoretic Metrics

Information-theoretic approaches offer a fundamentally different perspective, treating image quality assessment as a problem of quantifying the amount of perceptually relevant information preserved in the distorted image. These models are rooted in natural scene statistics and signal fidelity theory, where both the reference and distorted images are interpreted as stochastic signals [66]. The Information Fidelity Criterion (IFC) and the Visual Information Fidelity (VIF) index model the image source and distortion process probabilistically, estimating mutual information between the reference and distorted signals as mediated by models of the human visual system **Sheikh2006VIF**. This framework enables a content-aware assessment of quality that accounts for the statistical dependencies and perceptual importance of image structures.

The IFC models image patches in the wavelet domain using Gaussian scale mixture (GSM) models. It estimates the mutual information between the reference image x and the distorted image y conditioned on the distortion model and natural scene statistics:

$$\text{IFC}(x, y) = \sum_{i \in \Omega} I(C_{x,i}; C_{y,i} | z_i) \quad (2.31)$$

where $C_{x,i}$ and $C_{y,i}$ are wavelet coefficients of the reference and distorted images in patch i , and z_i is a local variance parameter estimated under a GSM model. The total information is accumulated over all image patches Ω .

The VIF index extends this by incorporating a model of the human visual system. It computes the ratio of information that can be extracted by a hypothetical observer from the distorted image versus the reference:

$$\text{VIF}(x, y) = \frac{\sum_{i=1}^N I(E_i; F_i)}{\sum_{i=1}^N I(E_i; G_i)} \quad (2.32)$$

Here, E_i represents the coefficients of the reference image, F_i those of the distorted image after HVS filtering, and G_i those of the reference after the same filtering. The numerator measures the information preserved in the distorted image, and the denominator the total information in the reference. Mutual information is computed under assumed Gaussian models of natural scenes and additive noise for distortion and perceptual masking.

Several variants of the VIF metric have been proposed to adapt the model to different domains and signal characteristics. The pixel-domain variant, VIFp [81], simplifies the original VIF model by operating directly on pixel intensities rather than wavelet coefficients. This avoids the need for multi-resolution decomposition and is computationally more efficient, making it suitable for real-time or resource-constrained applications. VIFp retains the same information fidelity framework, estimating mutual information between corresponding local patches.

Another extension is VIFc, which extends the VIF model to handle color images **Sheikh2006VIF**. Instead of converting the image to grayscale, VIFc applies the information fidelity model to each color channel, often in the YCbCr color space. A weighted fusion of channel-wise VIF scores is then used to produce a final quality estimate:

$$\text{VIFc}(x, y) = \sum_{k \in \{Y, Cb, Cr\}} w_k \cdot \text{VIF}_k(x, y) \quad (2.33)$$

where w_k are empirically determined weights that reflect the perceptual importance of each component. Typically, the luminance channel (Y) receives the highest weight due to its dominant role in human perception.

These variants preserve the conceptual integrity of the original VIF model while offering improved flexibility for different input modalities and computational budgets.

Deep Learning-based Metrics

Learning-based full-reference IQA models leverage deep neural networks to capture perceptual similarity in a data-driven manner. Unlike traditional models that rely on handcrafted features or analytic formulations of human perception, these methods operate in learned feature spaces derived from large-scale image datasets. The central assumption is that perceptual similarity can be approximated by comparing intermediate activations of pretrained convolutional neural networks (CNNs) [82]. The Learned Perceptual Image Patch Similarity (LPIPS) metric exemplifies this approach by computing a weighted L_2 distance between feature maps extracted from networks such as VGG or AlexNet. Subsequent models, such as DISTS [64], refine this idea by balancing structural and texture similarity through adaptive weighting schemes. Other approaches, like WaDIQaM [83], train task-specific regressors over deep features extracted from both the reference and distorted images. These models achieve high correlation with human opinion scores, particularly in cases involving complex or perceptually subtle distortions, but often require careful normalization and calibration of feature space distances.

The LPIPS metric computes the distance between deep feature maps of a reference image x and a distorted image y as follows:

$$\text{LPIPS}(x, y) = \sum_l \frac{1}{H_l W_l} \sum_{h=1}^{H_l} \sum_{w=1}^{W_l} \|w_l \odot (\hat{f}_l^x(h, w) - \hat{f}_l^y(h, w))\|_2^2 \quad (2.34)$$

where $\hat{f}_l^x$ and $\hat{f}_l^y$ are the normalized feature maps at layer l for images x and y , respectively, with spatial dimensions $H_l \times W_l$. The weights w_l are learned scalars for each channel, and $\odot$ denotes element-wise multiplication.

The DISTS metric combines feature similarity and texture similarity between corresponding feature maps:

$$\text{DISTS}(x, y) = \sum_l \alpha_l \cdot S_l(x, y) + \beta_l \cdot T_l(x, y) \quad (2.35)$$

where $S_l(x, y)$ is the structure similarity component computed as the cosine similarity between deep features at layer l , and $T_l(x, y)$ is the texture similarity component, often based on the mean and variance of feature activations. The coefficients α_l and β_l are learned to balance structure and texture contributions for each layer l .

WaDIQaM-FR learns a patch-based quality prediction model using paired deep features from the reference image x and the distorted image y . Given a patch pair (x_i, y_i) , deep features are extracted using a shared-weight CNN encoder, and the resulting representations are concatenated and passed through a regression network to predict a local quality score q_i . The final quality score is the weighted average over all patches:

$$Q(x, y) = \sum_{i=1}^N w_i \cdot q_i \quad (2.36)$$

where $q_i = f_\theta(x_i, y_i)$ is the predicted quality for patch i , w_i is a learned spatial weight indicating the perceptual relevance of patch i , and N is the total number of patches. The function f_θ denotes the trained regression model with parameters θ .

During training, the network minimizes the error between predicted quality scores and human-annotated MOS or DMOS labels using an appropriate loss function (e.g., MSE or Huber loss). Unlike LPIPS or DISTS, WaDIQaM does not rely on pretrained networks, allowing it to adapt feature representations to the task of quality prediction.

In summary, full-reference IQA models span a spectrum from simple error-based metrics to perceptually and statistically grounded approaches. Fidelity-based methods offer computational efficiency but lack alignment with human perception. Perceptual similarity models incorporate structural and saliency cues to improve correlation with subjective quality. Information-theoretic metrics formalize quality as mutual information preservation under natural scene statistics. Learning-based models leverage deep features or end-to-end training to approximate percep-

tual similarity in high-dimensional spaces. Each class reflects a trade-off between interpretability, perceptual fidelity, and computational complexity, making their suitability highly context-dependent.

2.2.2 No-Reference IQA

Traditional NR-IQA

Among traditional NR-IQA techniques, PIQE [84] (Perception-based Image Quality Evaluator) and NIQE [85] (Natural Image Quality Evaluator) are widely used due to their computational simplicity. PIQE begins by dividing the input image into non-overlapping 16×16 blocks, denoted B_i , and identifying distorted blocks based on edge content and local variance thresholds. For each block, it computes perceptual features using the gradient magnitude:

$$S_i = \frac{1}{|B_i|} \sum_{(x,y) \in B_i} \sqrt{\left(\frac{\partial I}{\partial x}\right)^2 + \left(\frac{\partial I}{\partial y}\right)^2}, \quad (2.37)$$

and noise, estimated by subtracting a low-pass filtered (LPF) version of the block:

$$N_i = \text{std}(B_i - \text{LPF}(B_i)). \quad (2.38)$$

The global PIQE score is computed via a weighted aggregation over the distorted blocks, $\mathcal{D}$:

$$\text{PIQE} = \frac{1}{|\mathcal{D}|} \sum_{i \in \mathcal{D}} w_i \cdot (\alpha S_i + \beta N_i + \gamma C_i), \quad (2.39)$$

where w_i are confidence weights and α, β, γ are scaling factors for sharpness, noise, and contrast, respectively. The final score is scaled between 0 (best quality) and 100 (worst quality).

In contrast, NIQE is grounded in natural scene statistics (NSS), using a statistical deviation model to quantify perceptual degradation. First, it applies Mean Subtracted Contrast Normalization (MSCN) to locally standardize luminance:

$$\hat{I}(x, y) = \frac{I(x, y) - \mu(x, y)}{\sigma(x, y) + \epsilon}, \quad (2.40)$$

from which it extracts statistical features associated with Generalized Gaussian Distributions (GGD) and Asymmetric GGD (AGGD). A multivariate Gaussian (MVG) model with mean μ_r and covariance Σ_r is estimated to a set of pristine images. During inference, the Mahalanobis distance between the test image features $\mathbf{f}_t$ and the natural image model is used to compute the NIQE score:

$$\text{NIQE}(\mathbf{f}_t) = \sqrt{(\mathbf{f}_t - \mu_r)^T \Sigma_r^{-1} (\mathbf{f}_t - \mu_r)}. \quad (2.41)$$

This formulation enables NIQE to operate in a completely opinion-unaware and unsupervised fashion, relying solely on deviations from natural image statistics to infer perceptual quality.

Facial Image Quality Assessment

FIQA refers to the estimation of biometric utility from face images, typically in the context of face recognition, verification, or detection pipelines. Unlike generic NR-IQA, FIQA does not aim to measure aesthetic or perceptual quality, but rather the suitability of a face image for recognition purposes [86], [87]. This quality is influenced by a range of factors, including resolution, pose, occlusion, blur, compression, and illumination.

Traditional FIQA methods relied on handcrafted features such as sharpness, symmetry, or inter-eye distance [88]. Recent models leverage deep face embeddings extracted from recognition networks [42], [89]. These models typically apply a regression or ranking loss to map features to quality scores correlated with recognition accuracy.

FIQA is an inherently task-dependent quality problem. Unlike general-purpose IQA, it must account for the characteristics of the recognition model and dataset. Furthermore, FIQA methods often correlate poorly with perceptual quality metrics, as an image may appear visually high-quality but remain unsuitable for matching due to pose or occlusion. This motivates the need to explore perceptually grounded IQA models tailored to face data, and to investigate how traditional metrics can be adapted, fused, or compared against biometric-specific quality indicators.

In contrast to traditional statistical NR-IQA methods, recent approaches such as SER-FIQ [42] (Stochastic Embedding Robustness for Face Image Quality) and MagFace [41] adopt deep learning-based strategies tailored specifically for facial image quality. SER-FIQ builds on the intuition that high-quality facial images produce consistent embeddings under stochastic dropout perturbations, while low-quality images result in more variable and unstable representations. Given a face image, a pre-trained face recognition model (e.g., ArcFace) with dropout enabled generates T stochastic embeddings $\{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_T\} \in \mathbb{R}^d$. The pairwise cosine similarities between these embeddings are then computed:

$$\text{sim}(\mathbf{e}_i, \mathbf{e}_j) = \frac{\mathbf{e}_i \cdot \mathbf{e}_j}{\|\mathbf{e}_i\| \|\mathbf{e}_j\|}, \quad \forall i, j \in \{1, \dots, T\}, i < j. \quad (2.42)$$

The final SER-FIQ score is derived from the mean or standard deviation of the similarity matrix, often defined as:

$$\text{SER-FIQ} = \frac{1}{\binom{T}{2}} \sum_{i < j} \text{sim}(\mathbf{e}_i, \mathbf{e}_j), \quad (2.43)$$

where higher scores indicate more stable (and thus higher-quality) facial representations. This method is fully unsupervised and exploits intrinsic model uncertainty as an indicator for quality.

MagFace, on the other hand, is a supervised approach that explicitly learns a quality-aware embedding space. It introduces a margin-adaptive loss that couples facial feature magnitude

with image quality. For an embedding $\mathbf{e} \in \mathbb{R}^d$, its L_2 -norm $\|\mathbf{e}\|$ is used as a measure for quality. The classification loss is modified as:

$$\mathcal{L}_{\text{MagFace}} = -\log \frac{e^{s \cdot (\cos(\theta_y + m(\|\mathbf{e}\|)))}}{e^{s \cdot (\cos(\theta_y + m(\|\mathbf{e}\|)))} + \sum_{j \neq y} e^{s \cdot \cos(\theta_j)}}, \quad (2.44)$$

where θ_y is the angle between $\mathbf{e}$ and the weight vector of the correct class, s is a scaling factor, and $m(\|\mathbf{e}\|)$ is a dynamic margin that increases with quality. The final MagFace quality score is proportional to the magnitude $\|\mathbf{e}\|$, constrained during training to lie within a fixed interval $[l, u]$ for regularization. Unlike SER-FIQ, MagFace learns to embed quality-awareness directly into the feature space through supervision, enabling both verification and quality prediction in a unified framework.

2.2.3 Fusion-Based IQA Models

To address the perceptual limitations of individual image quality metrics, several fusion-based approaches have been proposed. Liu et al. [63] introduced a multi-method fusion (MMF) framework that linearly combines full-reference IQA scores via supervised regression to better approximate MOS. Henniger et al. [39] developed a Random Forest model trained on handcrafted features derived from ISO-compliant facial images, improving performance in biometric settings. These works demonstrated that integrating complementary quality cues can significantly enhance perceptual alignment, outperforming standalone metrics in correlation with human judgment [90].

In parallel, the scarcity of large-scale human-labeled datasets has motivated weakly supervised learning strategies. Chen et al. [47] generated pseudo-MOS labels by averaging outputs of multiple FR-IQA metrics. RankIQA [43] applied relative ranking supervision on synthetically degraded images to learn ordinal quality representations. Wu et al. [91] used cascaded convolutional regressors trained on pseudo-MOS labels, demonstrating that pseudo-supervision can bootstrap learning when subjective ground truth is limited.

These developments support the feasibility of learning perceptual quality through fusion, either via model ensembles or by generating training supervision. Our approach builds on this principle: we construct a regression-based fusion model that aggregates multiple FR-IQA scores to predict perceptual quality, using human-labeled MOS as supervision. This model is then applied to a larger unlabeled dataset to generate pseudo-MOS scores, which in turn are used to train a no-reference regressor. This hybrid full-to-no-reference framework enables scalable, perceptually grounded quality estimation even in the absence of pristine reference images.

2.3 Steganography

Steganography has evolved significantly with the rise of digital media and advanced compression algorithms, leading to a variety of embedding methods and detection strategies. Classical steganographic methods can be broadly categorized into spatial, frequency, and adaptive domain techniques. Spatial domain methods directly manipulate pixel values, most notably through Least Significant Bit (LSB) substitution [92], to encode binary data within an image. Frequency domain methods operate on transformed representations of the image, using tools such as the Discrete Cosine Transform (DCT) or Discrete Wavelet Transform (DWT), embedding data in coefficients less sensitive to compression [93]. Adaptive methods further refine this by analyzing local characteristics of the image, dynamically choosing to embed regions to minimize perceptual distortion [94].

However, current methods cover a wide range of applications, there has been a growing interest in printer-proof steganography, which survives the printing and scanning process. This is particularly relevant in contexts where physical copies of images are distributed, such as MRTDs. The challenge lies in ensuring that the embedded information remains detectable and robust against distortions introduced by printing and scanning processes.

2.3.1 Printer-proof Steganography

Recent advances employ deep learning to design robust, end-to-end steganographic pipelines that simulate print-scan degradations during training. We highlight four such methods that represent the current state of the art in printer-proof steganography for natural and facial images. The printer-proof steganography methods used were based on Generative Adversarial Networks (GANs) [95] to encode and decode information, we can obtain various results depending on the method used.

StegaStamp

StegaStamp [38] introduced the first deep learning-based pipeline for robust steganography under real-world distortions. It jointly trains an encoder-decoder architecture with simulated perturbations, such as blur, color shift, projective warps, and JPEG compression, to mimic the print-scan process. A random bitstring is embedded into the image, and the decoder learns to retrieve it despite these degradations. The training loss combines a cross-entropy bit loss, an L_2 reconstruction loss, and a perceptual LPIPS loss to preserve visual quality. StegaStamp showed that it is possible to reliably recover short messages (e.g., 56 bits) from physically printed and

scanned images, setting a benchmark for printer-proof robustness.

CodeFace

CodeFace [37] extends StegaStamp with a focus on facial images used in ID documents. It introduces facial-specific modules such as a Spatial Transformer Network (STN) for geometric alignment and a perceptual identity-preserving loss based on FaceNet embeddings. This ensures that the stego face remains visually and biometrically consistent with the original. The network is trained adversarially, with a discriminator encouraging naturalness and a decoder optimizing message recovery under print-scan distortions. CodeFace proves effective for embedding messages in high-resolution facial portraits, making it suitable for privacy-preserving biometric IDs.

RiemStega

RiemStega [96] innovates by introducing a Riemannian manifold-based loss. Instead of comparing pixel values, it represents images through symmetric positive definite (SPD) covariance matrices and minimizes the affine-invariant Riemannian distance between the cover and stego image descriptors. This statistical approach preserves global structural and texture patterns more robustly under degradation. The method maintains high visual fidelity while increasing message recoverability post-printing, and demonstrates strong performance on both generic and facial image datasets.

StampOne

StampOne [97] incorporates frequency-domain awareness by applying DWT and gradient maps to both image and message during encoding. The model balances frequency bands via a learned attention mechanism and includes frequency-domain discriminators in its loss functions. This results in encoded images with spectral properties closely matching those of the original, enhancing resilience to printer-related distortions such as color shifts and sensor noise. StampOne outperforms prior methods in both visual similarity and decoding accuracy, especially for high-frequency facial features.

3 Methodology

3.1 Dataset

Our dataset is derived from the publically available Face Research Lab London [98] (FRL) set, comprising 102, 1350×1350 , full coloured images of frontal, ICAO-compliant adult faces. Self-reported age, gender and ethnicity are included. Attractiveness ratings (on a 1–7 scale from “much less attractiveness than average” to “much more attractive than average”) for the faces from 2513 people (ages 17–90) are included as well. The FRL dataset was selected for its high-fidelity ICAO-compliant images, controlled acquisition conditions, and extensive demographic annotations, which are crucial for analyzing perceptual quality and potential demographic biases in subjective ratings. Each image was encoded using four printer-proof steganographic methods, each applied at nine different intensity levels, $x \mid x = 0.6 + 0.1 \times k, k \in \{0, \dots, 8\}$, yielding a total of 3,672 distorted images.

The dataset was partitioned to support both supervised learning and independent evaluation. A small, demographically diverse subset of 15 identities, shown in Fig. 3.1 was annotated with MOS through subjective tests. This set was split into a training portion (12 identities, Fig. 3.1a) used to fit the fusion model, and a disjoint test portion (3 identities, Fig. 3.1b) held out for final evaluation. The remaining 87 identities formed the unlabeled set, to which pseudo-MOS were later assigned. Together, the annotated and pseudo-labeled subsets were used to train the NR-IQA model. A summary of these partitions, including the number of subjects and images per subset, is presented in Table 3.1.

The steganographic distortions are visible in Fig. 3.2, which shows examples of distorted facial images from each method. The distortions are applied to the original images, and the resulting stego images are used for both subjective evaluation and training of the NR-IQA model. The selected steganographic methods represent diverse classes of distortion processes (geometric, color-based, local texture perturbation) commonly encountered in practical steganographic applications. The chosen intensity levels ensure a broad perceptual range from barely noticeable to clearly visible distortions.

Table 3.1: Partitioning of the steganographically distorted dataset.

Subset	Subjects	Images	Purpose
MOS train set	12	432	Train FR fusion model
MOS test set	3	108	Final evaluation (disjoint)
Pseudo-MOS set	87	3,132	Generate pseudo-MOS labels
NR train set (total)	99	3,564	Train NR model (MOS train + pseudo-MOS)
Total	102	3,672	Full dataset (all stego levels)

Figure 3.2: Steganographically distorted facial images from each method.

3.2 Collection of Subjective Scores

We followed the ITU-R BT.500–15 [45] recommendation and adopted the Single Stimulus (SS) method. The test was implemented using a custom Django web application seen in Fig. 3.3. Prior to the test session, participants signed an informed consent form and filled out a registration form providing demographic and environmental information such as age, gender, education, country of origin and ethnicity, and others. Each image was shown individually, with no time limit. Ratings were submitted using a labeled slider, and automatic saving ensured session robustness.

Each image in the MOS set was evaluated approximately 30 times by human observers, resulting in over 14,000 ratings. We had around 200 participants, each session lasted about 22 minutes and included roughly 70 evaluations. Table 3.2 summarizes the demographic profile of the participant pool. Following the session, outlier observers were identified and removed using both Kurtosis-based and correlation-based post-screening methods described in ITU-R BT.500–15 [45], resulting in the exclusion of one participant.

The database was implemented using the Django web framework, which provides an object-relational mapping (ORM) layer that directly maps Python model classes to database tables. The ORM also enforces data integrity constraints and simplifies querying for statistical analysis. The database backend used was PostgreSQL.

The database schema was designed to ensure structured storage and traceability of all subjective quality evaluation data. Fig. 3.4a presents the conceptual data model, which defines the main entities and their relationships. The profile entity stores participant metadata, including age, gender, education, ethnicity, country of origin, and device used. The `ss_session` entity models individual test sessions and is linked to both the participant profile and the dataset being evaluated. The image entity encodes each image’s filename, associated distortion type (`distortion_name`), and distortion level (`distortion_level`). The test entity stores individual subjective ratings, including the precise timestamp of submission, linked to both the session and the image presented. An auxiliary `user_feedback` entity captures optional, anonymous, observer comments and critiques.

The physical implementation of this schema, shown in Fig. 3.4b, is realized as a relational database with explicit foreign key constraints to ensure referential integrity. The `dataset_id` and `profile_id` fields in `ss_session` formally enforce the linkage to specific datasets and participants. The test table connects each subjective rating to its session (`ss_session_id`) and image (`image_id`), enabling consistent aggregation of ratings into a statistical descriptor such as MOS and confidence intervals per image and per distortion level. The relational model also facili-

Figure 3.4: Conceptual and physical representations of the database schema.

3.3 Debiasing of Subjective Scores

To correct for demographic bias in the subjective scores, we followed a procedure inspired by prior work on bias correction in perceptual tasks [99], where we applied a residualization method based on linear modeling. An ordinary least squares (OLS) regression was fit to the MOS values, using observer and image attributes, and their pairwise interactions as categorical predictors. The fitted bias components were subtracted from the original scores, and the residuals were mean-centered to preserve the global score distribution. As shown in Table 3.3, several factors exhibit statistically significant effects on the MOS prior to residualization, notably observer and subject ethnicity. After applying the residualization procedure, these effects disappear, as confirmed by an ANOVA test showing no significant impact from any individual factor. The corrected MOS labels are then used as ground truth in all supervised stages of the pipeline to ensure fairness and reduce the influence of socially conditioned priors.

Table 3.3: ANOVA [100] results for observer and image attributes. Before debiasing, several factors show statistically significant effects on MOS, p-value < 0.05 . After residualization, all main effects show no significant impact, confirming the effectiveness of the debiasing procedure.

Factor	p-value	p-value (residualized)
Observer gender	0.022	0.9930
Observer ethnicity	8.44×10^{-4}	1
Subject gender	1.60×10^{-3}	0.9722
Subject ethnicity	7.36×10^{-3}	1
Observer gender $\times$ Subject gender	0.6417	0.6417
Observer ethnicity $\times$ Subject ethnicity	0.0582	0.0582

3.4 Correlation of FR-IQA Metrics with Human Perception

We compute 40 FR-IQA scores for each distorted image in the dataset and compare them against the corresponding MOS, as seen in Fig. 3.5. Several metrics exhibit strong linear trends with MOS, while others are poorly aligned or even negatively correlated. For a detailed description of these metrics, we refer the reader to [101].

Figure 3.5: Scatter plots illustrating the relationship between MOS and 40 individual full-reference IQA metrics. The red line represents a smoothed local trend curve.

3.5 Fusion of FR-IQA Metrics for Pseudo-MOS Estimation

To identify which metrics align best with human perception, we compute both the Pearson Linear Correlation Coefficient (PLCC) and the Spearman Rank-Order Correlation Coefficient (SRCC) [102] which respectively quantify the linearity and monotonicity of the relationship between metric scores and MOS. To determine the appropriate number of metrics to retain for fusion, we applied Singular Value Decomposition (SVD) and the Picard criterion [103]. Metrics are first ranked by the average of their PLCC and SRCC with MOS. After normalizing the feature matrix, SVD revealed that six components capture 95% of the total variance, as shown in Fig. 3.6a, indicating an optimal dimensionality of $k = 6$.

To validate this truncation point, we examined the Picard plot in Fig. 3.6b, which compares singular values with the target projections. The stable ratio in the tail confirms that six components provide a good balance between expressiveness and stability. This supports a compact, informative subset of FR-IQA metrics.

After selecting the top $k = 6$ FR-IQA metrics, we trained a diverse set of supervised regressors to map these features to subjective MOS scores. The models included both linear and non-linear types:

- Linear models: Linear Regression [104], Ridge Regression [105], Bayesian Ridge [106], ElasticNet [107].
- Kernel-based: Support Vector Regression [108] (SVR).
- Ensembles: Random Forest [109], Extra Trees [110], Gradient Boosting [111], HistGradientBoosting [112].
- Boosted Trees: XGBoost [113], LightGBM [114], CatBoost [115].

Each regressor was trained using five-fold cross-validation with an exhaustive grid search over predefined hyperparameter spaces. The best model, CatBoost, optimal configuration was: depth = 8, iterations = 500, learning rate = 0.05, and L_2 regularization = 1. This trained regressor is then applied to the unlabeled portion of the dataset (3,132 distorted images), generating pseudo-MOS.

(a) Cumulative variance explained by SVD components.

(b) Magnitude of singular values and projected response.

Figure 3.6: SVD-based analysis of the FR metric space. The cumulative explained variance (a) guides the choice of dimensionality, while the Picard criterion (b) illustrates stability near $k = 6$.

3.6 Training a No-Reference IQA Model from Pseudo-MOS

To enable NR quality prediction, we train a deep regression model end-to-end using pseudo-MOS scores as targets. The architecture is based on a ResNet-18 backbone [116] pretrained on ImageNet [117], with its final classification layer replaced by a lightweight multi-layer perceptron (MLP) regressor [106]. All layers are fine-tuned during training to learn perceptual quality representations specific to our task. The training set consists of distorted facial images paired with either pseudo-MOS, from the FR fusion, or real MOS labels, when available. The model is optimized using MSE and evaluated on the disjoint, MOS test set of labeled images. Once trained, the model infers image quality solely from the distorted input, enabling NR assessment aligned with human perception.

3.7 Results

3.7.1 Full-Reference Fusion Metric Performance

To interpret feature contributions, we used SHAP [118] (SHapley Additive exPlanations) values derived from CatBoost’s internal structure. SHAP values quantify how much a feature pushes the model’s output away from the expected value. As shown in Fig. 3.7, MS-SSIM [119] (Multiscale SSIM) and UQI [120] (Universal Quality Index) had the largest positive impact on predictions, while PSNR-B [121], VIF[61], (PSNR-Blocking), PSNR [122] and SNR [60] (Signal-to-Noise Ratio) contributed with moderate influence. The color encoding further highlights how high

Figure 3.7: SHAP summary plot for $k = 6$, generated from the best CatBoost model.

Table 3.4: Performance of our Fusion metric and the selected FR-IQA metrics. Higher PLCC and SRCC indicates better correlation with MOS. Lower MSE and MAE indicate more accurate quality estimates.

Metric	PLCC	SRCC	MSE	MAE
Fusion (CatBoost)	0.8881	0.8893	65.07	6.160
MS-SSIM	0.7712	0.8489	2542	47.27
PSNR	0.8009	0.8132	420.7	16.57
PSNR-B	0.7996	0.8126	434.8	16.84
SNR	0.7931	0.8047	493.9	18.08
VIF	0.7723	0.7671	2584	47.75
UQI	0.6866	0.8085	2540	47.24

and low feature values affect the model output.

When comparing the fusion metric with the individual FR metrics, Table 3.4 shows that the fusion metric outperformed all individual metrics in terms of PLCC, SRCC, MSE and MAE. This demonstrates the effectiveness of our approach in combining multiple FR metrics to improve overall performance.

3.7.2 No-Reference Regression Model Performance

We refer to our NR-IQA model as pMOS-Face (pseudo-MOS for Face), reflecting its use of pseudo-MOS labels generated from the FR fusion model and its evaluation on faces. This framework can be adapted to other datasets, provided that a small set of images with human labels is available for training the FR fusion model. Fig. 3.8 shows two evaluation scenarios: in Fig. 3.8(a), the model’s predictions are compared against the pseudo and ground-truth MOS

Table 3.5: Performance of our pMOS-Face compared to standard NR-IQA baselines.

Metric	PLCC	SRCC	MSE	MAE
pMOS-Face (ours)	0.9285	0.9345	120.6	9.158
NIQE	0.7536	0.7431	6859	82.62
PIQE	0.2993	0.3114	3297	57.05
SER-FIQ	-0.1648	-0.1542	123.5	9.230
MagFace	-0.6095	-0.6362	4437	66.24

used during training, yielding a PLCC of 0.9285, SRCC of 0.9345, MSE of 120.2, and MAE of 9.158. Fig. 3.8(b) shows the predictions compared against the MOS test set, resulting in a PLCC of 0.9679, SRCC of 0.9691 and MSE of 35.34 and MAE of 4.743. These results confirm both generalization to unseen human labels and alignment with the pseudo-supervision used for training.

Figure 3.8: Evaluation of our NR-IQA model. Panel (a) shows performance on the training set with pseudo and ground-truth MOS; panel (b) shows performance on the disjoint test set with ground-truth MOS.

The results indicate that our model is more effective in predicting perceptual quality than classical NR-IQA metrics such as NIQE [85] and PIQE [84], as well as task-specific approaches like SER-FIQ [42] and MagFace [41]. This highlights the robustness of our weakly supervised strategy for NR-IQA on steganographically degraded facial images. Quantitative results are reported in Table 3.5.

When considering a more generalized use, where observer bias is not accounted for, our NR-IQA model shows a major improvement over the baselines. This is particularly relevant for task specific applications, where the model can be trained on a small set of images with human labels

and then applied to larger datasets without the need for additional supervision. This approach allows for a more scalable and efficient solution not only for FIQA but also for other domains where reference images are not available.

3.8 Conclusion and Future Work

We proposed a Full-to-No-Reference framework for FIQA that predicts image quality in the absence of reference images by leveraging a pseudo-MOS supervision strategy. Our method first trains a FR fusion model to regress human perceptual judgments on a labeled subset (10% of the dataset), generating pseudo-MOS labels for a larger unlabeled dataset. These forged labels are then used to train a deep NR regressor, enabling quality prediction from distorted images alone. This two-stage pipeline effectively bridges the gap between fully supervised FR-IQA and reference-free NR-IQA approaches.

Beyond the development of our NR IQA metric, the proposed framework offers a flexible foundation for constructing a variety of task-specific models. By enabling scalable, perceptually grounded supervision with limited ground-truth annotations, our approach can facilitate quality-aware training in applications such as GANs, forensic imaging, and domain-adapted biometric pipelines.
